Non-steady-state kinetic studies reveal that the elimination of HBr from 2-(p-nitrophenyl)ethyl bromide (NPEB) in ethanol or methanol containing the corresponding alkoxide ions is inconsistent with the concerted E2 mechanism. Extent of reaction–time profiles for these reactions deviate significantly from the expected response for the E2 mechanism and extent-of-reaction-dependent apparent deuterium kinetic isotope effects (KIEs) were observed. The kinetic data are consistent with the reversible consecutive second-order mechanism, eqn. (1). The formation of the carbanion is rate determining by virtue of the fact that loss of bromide ion (k_b) is rapid compared to protonation of the carbanion (k_p). The latter precludes D/H exchange during the elimination reactions of NPEB-2-d_2.

The elimination reactions of NPEB in ethanol containing ethoxide ions is a classic example of a reaction believed to take place by a concerted E2 mechanism. Recent studies published by the Thibblin group4–9 and others19–19 continue to provide significant new mechanistic detail. These studies have been concerned with the factors influencing elimination reactions in the border-line region between the E1CB and E2 mechanisms. The effect of structure on reactivity, kinetic isotope effects, and Bronsted parameters has been heavily relied upon in these discussions. Our recent non-steady-state kinetic studies20–26 have revealed that many organic reactions previously believed to follow simple second-order kinetics follow the reversible consecutive second-order mechanism and do not reach a steady state before late in the first half-life. These include proton transfer reactions of methylelarene radical cations,21,26,27 proton transfer between a nitroalkane and hydroxide ion,24 hydride transfer of an NADH model compound,25 and the S_2 reaction between the p-nitrophenoxide ion and methyl iodide in aqueous acetonitrile.26 We anticipated that our non-steady-state kinetic method would be applicable to the E2–E1CB manifold of reactions.

Results and discussion

The analysis of extent of reaction–time profiles is an effective means for distinguishing between the irreversible second-order mechanism (2) and the reversible consecutive second-order mechanism (3) providing that kinetic data in the pre-steady-state time period can be accessed.24 Once steady-state is reached, the two mechanisms are kinetically indistinguishable. In our non-steady-state kinetic studies we determine two parameters, k_{int}/k_{obs} and t_{obs}/t_{int}, which serve as mechanism probes. The first is defined as the ratio of the initial rate constant (k_{int}) during the extent of reaction ranging from 0 to 0.05 divided by the apparent pseudo first-order rate constant (k_{obs}) in the range from 0.05 to 0.50. The second is the time ratio, which corresponds to time at extent of reaction 0.50 (t_{obs}) divided by that at extent of reaction equal to 0.05 (t_{int}). For mechanism (2) k_{int}/k_{obs} is equal to 1.00 and t_{obs}/t_{int} is equal to 13.51 under pseudo-first-order conditions with reactant B in large excess. In the early states of a reaction following mechanism (3), increase in [C] lags behind the decrease in [A]. When the increase in [C] is monitored under these conditions, k_{int} will be diminished and t_{obs} will be increasing giving rise to k_{int}/k_{obs} less than unity and t_{obs}/t_{int} less than 13.51. Just how large these deviations will be will depend upon the relative magnitudes of the rate constants k_p, k_0, and k_p' and in the limit both values approach those for mechanism (2).

For elimination reactions, eqn. (2) corresponds to the concerted E2 mechanism and eqn. (3) to the E1CB mechanism in which 1 is the carbanion.

The data in Table 1 summarizes the mechanism probe parameters observed for the elimination of HBr from NPEB and NPEB-2-d_2 in EtOH and in MeOH containing the corresponding alkoxide ions at 293 K. The last 2 columns in Table 1 show that both k_{int}/k_{obs} and t_{obs}/t_{int} deviate drastically from the theoretical values for mechanism (2), 1.00 and 13.51, respectively. The extent of reaction–time profiles for the reactions of NPEB and NPEB-d_2 in ethanol are illustrated in Figs. 1 and 2, respectively. The experimental data are shown as solid squares and the solid lines represent the expected response for mechanism (2).

\[ A + B \xrightarrow{k_1} \frac{1}{k_2} C \]

\[ A + B \xrightarrow{k_{int}} \frac{1}{k_{obs}} C \]

\[ NPEB = 2-(p\text{-}nitrophenyl)ethyl bromide \] As defined in the text. Each value was derived from 40–60 extent of reaction–time profiles processed from digitally smoothed absorbance (335 nm)–time data (2000 points) generated with either a Hi-Tech model SF-61 or a SF-62 stopped flow instrument. Extent of reaction defined as [NS]/[NPEB], where NS is the product, 2-p-nitrostyrene.

The data in Table 1 summarizes the mechanism probe parameters observed for the elimination of HBr from NPEB and NPEB-2-d_2 in EtOH and in MeOH containing the corresponding alkoxide ions at 293 K. The last 2 columns in Table 1 show that both k_{int}/k_{obs} and t_{obs}/t_{int} deviate drastically from the theoretical values for mechanism (2), 1.00 and 13.51, respectively. The extent of reaction–time profiles for the reactions of NPEB and NPEB-d_2 in ethanol are illustrated in Figs. 1 and 2, respectively. The experimental data are shown as solid squares and the solid lines represent the expected response for mechanism (2). The data in Table 1 and Figs. 1 and 2 force the
derivable from extent of reaction measurements. This is illustrated by the plots in Figs. 3 and 4. Once again the experimental data are shown as solid squares and the solid lines are theoretical data for mechanism (3). In all cases, reasonably close correspondence between experimental and theoretical data are observed. The fitting procedure which involved systematically changing the rate constants and minimizing the difference between experimental and theoretical data until a best fit was obtained invariably resulted in \( k_i \) very nearly equal to \( k_{app} \) defined by eqn. (4). Since \( k_i \) can only equal \( k_{app} \) when \( k_b \) is zero, the fitting results require that \( k_b \) is very small.

\[
k_{app} = k_i k_p/(k_p + k_b)
\]  

(4)

It is likely that the \( k_b \) are non-zero but not large enough to influence the fitting of experimental to theoretical data. It should be pointed out that an additional constraint was applied during the fitting for the reactions of NPEB-d\(_2\) (Fig. 4) that consisted of assuming the value for \( k_p \) to be equal to that derived during the fitting of data for NPEB (Fig. 3).

The experimental \( (k_{app}) \) and best-fit \( (k_i \) and \( k_p \) ) rate constants derived from extent of reaction–time profiles in both solvent systems are summarized in Table 2. The features of most interest are (a) that the relatively small \( k_p \) values are about two orders of magnitude greater than the corresponding \( k_i \) values and (b) \( k_b \) are about 15 times as great in ethanol as compared to methanol. Another feature of interest of the experimental data is that the apparent deuterium kinetic isotope effects (KIE\(_{app}\)) are extent-of-reaction dependent. This is illustrated by the plots in Fig. 5a (EtOH) and 5b (MeOH).

* Mechanism (3), [A] = 0.001 M, [B] = 1 M, \( k_p = 1 \text{ M}^{-1} \text{s}^{-1}, \) \( k_k = 0. \)

In order to provide further insight into how the relative values of \( k_p \) and \( k_k \) influence the magnitudes of the mechanismic probes, \( (k_{\text{full}}/k_p) \) and \( t_{1/2,\text{full}}/t_{1/2,\text{k}} \), theoretical data were calculated for the hypothetical case where \( k_{\text{full}} = k_p \) (1 M \(^{-1} \text{s}^{-1} \)), \( k_k = 0 \), and \( k_p \) was varied over a wide range. These results are summarized in Table 3. The most interesting feature of these data is that \( k_p \) approaches \( k_k \) when \( k_p/k_k \) is about 32 while \( k_{\text{full}} \) does not approach the \( k_k \) value until the ratio is nearly 10,000. This provides a very wide range of \( k_k \) values where \( t_{1/2,\text{full}}/t_{1/2,\text{k}} \) deviates significantly from the limiting value of 13.51.

Conclusions

Our primary conclusion from this preliminary study of the kinetics of elimination reactions is that the classic example of a concerted E2 mechanism, the elimination of HBr from NPEB, takes place by the E1CB mechanism accompanied by the formation of the carbanion which undergoes loss of bromide ion at a moderate rate. Our secondary conclusion, which is equally important, is that the non-steady-state mechanism probes are highly effective in the analysis of elimination reactions. Our recently developed data fitting procedure facilitates the resolution of the kinetics of the 2-step mechanism into the microscopic rate constants of the individual steps.
